Introduction

The treatment of rotator cuff tears has become one of the most common orthopaedic sports procedures [1,2]. While this operation has a low morbidity, it is not without risk for complications such as chondrolysis, athrofibrosis, nerve damage, and infection [3-7]. The development of a synovia-cutaneous fistula is another rare, but serious, complication that has been described after rotator cuff repair [7,8]. Synovia-cutaneous fistulas have been described as sequel of postoperative infections or suture reactions necessitating surgical debridement [8]. Fistula formation has also been attributed to a sequence of events that include excessive tension placed on the rotator cuff tendons and deltoide muscle during repair leading to inflammation, necrosis, and, ultimately, dehiscence over the glen humeral joint.

Synovia-cutaneous fistulas have been primarily reported as complications following arthroscopic knee surgery [7-11]. Literature describing the same complication after arthroscopic
shoulder surgery is limited. In these reports, the majority of synovia-cutaneous fistulas in the shoulder were successfully treated with debridement and primary closure; however, there have been reports of persistent fistulous connections requiring local flaps for obliteration [7,8]. While the use of a local rotational flap for shoulder reconstruction is widely reported, its role in the repair of synovia-cutaneous fistulas of the shoulder has not been well defined [4,5,7,8,12-14].

In this case series, two patients underwent shoulder arthroscopy for the treatment of rotator cuff tears and subsequently developed synovia-cutaneous fistulas of the shoulder. In both cases, debridement and primary closure were unsuccessful, and a local flap was required to obliterate the dead space created by a large facial dehiscence over the glen humeral joint. The purpose of this report is to present the local rotational flap as a treatment option for synovia-cutaneous fistulas of the shoulder and to emphasize the importance of recognizing when primary closure may not be sufficient for adequate repair.

CASE REPORTS

Case 1

A 67-year-old male with a past medical history significant for diabetes, hypertension, and hypercholesterolemia underwent a right rotator cuff and a biceps tendon repair complicated by the development of a draining sinus. In the six months following the repair, the patient underwent multiple attempts at irrigation, wound debridement, and negative pressure wound therapy. Due to the persistence of the draining fistula, the patient was referred to plastic surgery for evaluation and treatment. The patient’s physical exam was notable for a draining sinus tract with granulation tissue overlying the anterior surface of the right shoulder. The patient’s range of motion at the shoulder was severely limited, with an inability to elevate the shoulder beyond 90 degrees. An MRI of the shoulder revealed an anterior soft tissue tract extending from the wound surface to the cortex of the humeral head and T2 signal enhancement within the humeral marrow, concerning for underlying osteomyelitis. Based on the history and physical exam, the decision was made to proceed with extensive debridement and closure using vascuarized tissue.

The patient was brought to the operating room and the existing fistula tract was explored. It was noted to communicate with the glen humeral joint on the lateral aspect of the shoulder. The patient’s physical exam was not able to elevate the shoulder beyond 90 degrees, and an MRI of the shoulder revealed an anterior soft tissue tract extending from the wound surface to the cortex of the humeral head and T2 signal enhancement within the humeral marrow, concerning for underlying osteomyelitis. Based on the history and physical exam, the decision was made to proceed with extensive debridement and closure using vascuarized tissue.

The patient’s recovery was uneventful, and the patient was noted to have no recurrent fistula formation (Figure 4). The patient had improved shoulder range of motion with the ability to flex to 50 degrees and abduct to 65 degrees with minimal pain.

Case 2

A 63-year-old male with a past medical history significant for hypertension, tobacco use, and hyperlipidaemia was referred from an outside hospital for a postoperative wound complication following attempted open debridement of a torn rotator cuff approximately six weeks prior. At the time of initial surgery, the cuff tear was noted to be unreconstructable. Two weeks after the initial operation, a small opening draining a thin, non-odorous, pale yellow fluid developed at the previously healed shoulder incision. The wound was initially managed conservatively with local wound care in hopes that it would close by secondary intention. Over the next four weeks, however, both the size of the wound and the amount of drainage from the defect increased. The patient was then referred to plastic surgery for evaluation and treatment.

The patient’s physical exam revealed a full-thickness wound with surrounding rub or over the anterolateral aspect of the shoulder measuring 2 cm long x 1 cm wide with clear intraarticular extension (Figure 1). The patient’s range of motion at the shoulder (35 degrees of flexion and 60 degrees of abduction) was limited with significant pain on motion. Cultures of the fluid were obtained by joint aspiration and were negative for bacterial or fungal growth. The decision was made to proceed with extensive debridement and closure using vascuarized tissue.

The patient was brought to the operating room, and the existing fistula tract was explored. It was noted to communicate with the glen humeral joint on the lateral aspect of the shoulder (Figure 2). The decision was made to proceed with a pedicle my cutaneous latissimus flap (Figure 3). The flap was transposed into the defect created by debridement of the fistula tract and surrounding unhealthy tissue. The flap donor site was closed primarily. The patient was discharged on postoperative day five to home with a prescription for two weeks of Amoxicillin.

The patient’s recovery was uneventful, and the patient was noted to have no recurrent fistula formation (Figure 4). The patient had improved shoulder range of motion with the ability to flex to 50 degrees and abduct to 65 degrees with minimal pain.
In our report, one patient suffered from a chronically recurrent fistula of the shoulder despite multiple attempts at debridement and healing via secondary intention. The second patient was initially managed conservatively with wound packing before the decision was made to use myocutaneous flap for coverage of the shoulder defect; this patient did not undergo any prior attempts of debridement or primary closure of the defect. In both cases, following closure with a regional, vascularized flap, the patients experienced resolution of their chronically draining wounds, improved function in the affected limbs, and relief of pain.

The knee is the most commonly reported location to develop synovia-cutaneous fistulas following arthroscopic surgery, with an incidence of 0.5% to 1% [15-17]. In general, these patients respond well to immobilization of the knee or surgical excision of the fistulous tract and primary closure [8,15-17]. Similarly, of the available cases of synovia-cutaneous fistula reported in the shoulder, most have been managed with debridement and primary closure. In the setting of an underlying infection, primary closure of a synovia-cutaneous fistula is associated with higher rates of failure, prompting the use of a regional flap for successful wound coverage without recurrence of the fistula or abscess formation [18-22].

Similar to prior studies that detailed fistula tract formation in the knee secondary to an underlying surgical site infection or facial dehiscence, it is likely that the fistulous tract developed in our patients’ secondary to a either a postoperative infection or inflammation and necrosis of the rotator cuff tendons and tissues surrounding the glen humeral joint [8,18-22]. In both of our reported cases, the deltoid fascia was noted on perioperative imaging and intraoperative exam to be markedly dehisced and unsuitable for primary closure. As a result, a vascularized regional flap was chosen for wound coverage.

Prior studies have noted that similar to our findings, the draining shoulder sinuses communicated with the glen humeral joint [7,8]. The authors of these reports then hypothesized that the dehiscence of the rotator cuff and deltoid following repair allows for fistulous tract formation and that with shoulder motion, the synovial fluid is pumped to keep the fistula open [7,8]. In our series, both patients were successfully treated with adequate excision of the tract and appropriate flap coverage. Furthermore, both patients had improved range of shoulder motion and significant pain relief. In the setting of obvious joint involvement and/or a chronically infected synovia-cutaneous fistula, the decision to proceed directly to vascularized tissue coverage should be considered. If joint involvement or the presence of an underlying infection is uncertain, magnetic resonance imaging can aid in confirming the diagnosis, and either situation should prompt the discussion for potential use of a regional flap [11,23]. Shoulder reconstruction using a pedicle flap, such as the latissimus dorsi, is a widely accepted reconstructive option due to its reliability and ability to cover large wound defects with ease [24-26]. In cases of synovia-cutaneous fistulas, the use of a vascularized muscle flap is advantageous to obliterate dead space, treat osteomyelitis, and provide adequate bulky coverage of orthopaedic hardware [27,28]. The consideration for use of vascularized tissue is even more important for cases where there is suspicion for an underlying infection [29,30]. A study published by Mirzayan et al. details the use of my cutaneous flaps in 7 patients with deep shoulder infections [31].

Discussion

In our report, one patient suffered from a chronically recurrent fistula of the shoulder despite multiple attempts at debridement and healing via secondary intention. The second patient was initially managed conservatively with wound packing before the decision was made to use myocutaneous flap for coverage of the
study, the authors describe that inadequate soft tissue coverage of the glen humeral joint leads to the breakdown of the skin and subcutaneous tissue, and may lead to sinus tract formation. In these patients, the use of a muscle to cover the wound and fill the dead space can help provide a better seal for improved wound healing and infection control [31]. Previously reported flaps used for local coverage of deep shoulder wounds following rotator cuff repair include the latissimus dorsi and pectorals major, both of which have been reported to have favourable outcomes [29-31]. Modern reconstructive literature indicates that utilization of well vascularized fasciocutaneous flaps is equivalent to use of a muscle flap for wound coverage, and the choice of the regional flap is at the discretion of the reconstructive surgeon [32-36].

Conclusion
Deep infection following shoulder arthroscopy for rotator cuff repairs is a rare problem that can lead to the formation of a chronically draining synovia-cutaneous fistula that affects the glen humeral joint. Furthermore, the excessive tension placed on the rotator cuff tendons and deltoid during arthroscopic repair and the resultant inflammation may contribute to tissue necrosis and facial dehiscence over the glen humeral joint, allowing for fistula formation. When this complication occurs, it is imperative that a diagnosis is established as early as possible to avoid unnecessary procedures and prolonged use of antibiotics. Surgeons should be aware that when adequate soft tissue coverage cannot be accomplished over the glen humeral joint via primary closure, there are local flaps available to provide complete coverage over the joint.
